Any viable stellarator reactor will need to be nearly omnigenous, meaning the radial guiding-center drift velocity averages to zero over time for all particles. While omnignity is easier to achieve than quasihydromagneticity (Hym), we show here that several properties of quasihydromagnetic plasmas also apply directly or with only minor modification to the larger class of omnigenous plasmas. For example, concise expressions exist for the flow and current, closely resembling those for a tokamak, and these expressions are explicit in that no magnetic differential equations remain. A helicity \((M,N)\) can be defined for any omnigenous field, based on the topology by which \(B\) contours close on a flux surface, generalizing the helicity associated with quasihydromagnetic fields. For generalized quasipoloidal symmetry \((M = 0)\), the bootstrap current vanishes, which may yield desirable equilibrium and stability properties. A concise expression is derived for the radial electric field in any omnigenous plasma that is not quasihydromagnetic. The fact that the tokamak-like analytical calculations are possible in omnigenous plasmas despite their fully 3D magnetic spectrum makes these configurations useful for gaining insight and benchmarking codes. A construction is given to produce omnigenous \(B(\theta, \zeta)\) patterns with stellarator symmetry. \(\odot 2012\ American\ Institute\ of\ Physics.\)

I. INTRODUCTION

Nonaxisymmetric toroidal magnetic fields can provide intrinsically steady-state, disruption-free plasma confinement. However, unlike axisymmetric fields, nonaxisymmetric fields do not generally confine all trapped particle orbits. This shortcoming has a modest deleterious effect on energy confinement, which still follows scalings comparable to tokamak confinement due to turbulent transport.\textsuperscript{1} However, unconfined orbits will likely pose a serious problem in a reactor, where unconfined energetic alpha particles will collide with the first plasma-facing components. Consequently, one criterion of stellarator optimization in recent years has been the quality of collisionless particle confinement. The ideal limit in which all collisionless trajectories are confined is known as omnigenity (sometimes spelled omnigny). Omnigenity can be defined more precisely as the condition that the time average of \(v_m \cdot V \Psi\) along each field line vanishes for all values of magnetic moment \(\mu = v_m^2/(2B)\). Here, \(v_m = v^2 B \times \kappa/(\Omega B) + v^2 (B \times V B)/(2\Omega B^2)\) is the magnetic drift velocity, \(\kappa = b \cdot V b, b = B/B, B = |B|, \Omega = ZeB/(mc),\) is the gyrofrequency, \(Z\) is the species charge in units of the proton charge \(e, m\) is the mass, \(c\) is the speed of light, and \(2\pi \psi\) is the toroidal flux. As shown in the Appendix A, an equivalent definition of omnignity is that the longitudinal adiabatic invariant \(J = \frac{1}{2} v_c dL\) is a constant on a flux surface. Other equivalent definitions are the absence of a “1/\(v\)” regime of confinement, where \(v\) is the collision frequency, or an effective helical ripple of zero.

One method of obtaining omnignity in a nonaxisymmetric toroidal system is quasisymmetry, the design principle behind the Helically Symmetric eXperiment (HSX, Ref. 2) and National Compact Stellarator eXperiment (NCSX, Ref. 3.) Quasisymmetry is usually defined\textsuperscript{4} as the condition that the field magnitude \(B\) varies on a flux surface only through a fixed linear combination of the poloidal and toroidal Boozer angles,

\[ B = B(\psi, M0 - N \zeta), \]

for integers \(M\) and \(N\). Quasisymmetry can also be defined as \(B = B(\psi, M0 - N \zeta, b)\) for other coordinates \((\theta, \zeta, b)\) such as Hamada angles (as proved in the Appendix B), or by the coordinate-free conditions\textsuperscript{5} \(B \cdot V[(B \times \nabla \psi \cdot \nabla B)/(B \cdot V B)] = 0\) or \((\text{Ref. 6})\) \(V \cdot \nabla \psi \cdot V B = 0\). The Lagrangian \(L\) for guiding-center drift motion, when expressed in Boozer coordinates,\textsuperscript{7} only depends on \(B\) and not the vector components of \(B\). Consequently, an ignorable coordinate in \(B\) gives rise to a conservation law. The conserved quantity\textsuperscript{8,9} resembling canonical angular momentum, ensures each particle can only drift a distance on the order of a gyroradius away from a given flux surface, implying omnignity.

While every quasisymmetric field is omnigenous, not every omnigenous field is quasisymmetric. A proof by Cary and Shasharina at first appears to show the opposite conclusion, that a field which is both infinitely differentiable (analytic) and perfectly omnigenous must be quasisymmetric.\textsuperscript{7,10} However, the same authors point out that the proof is quite fragile: an analytic field that deviates from omnignity only slightly may depart from quasihydromagneticity by a great amount. (We will construct examples of such fields in Sec. V.) Thus, in practice, omnignity does not imply quasihydromagneticity. Consequently, to achieve good collisionless particle confinement, there is no need to strive for the strict condition of quasihydromagneticity when the weaker condition of omnignity is sufficient. While it is possible to find three-dimensional MHD...
equilibria that are reasonably close to quasisymmetry,\textsuperscript{2,9} lifting the demand of quasisymmetry widens the parameter space, allowing stellarators to be better optimized for other criteria.

One may still aim to achieve quasisymmetry for a different reason: In non-quasisymmetric plasmas, the parallel flow is determined by leading-order neoclassical processes, while in quasisymmetric plasmas, the parallel flow is determined by turbulence.\textsuperscript{5} As flows and flow shear may affect MHD modes and microinstabilities, quasisymmetric plasmas may have unique stability and turbulence properties, though more research is required to explore this notion.

Quasisymmetric fields provide an important and useful ideal limit for understanding nonaxisymmetric plasmas. In quasisymmetric fields, concise analytic expressions can be derived for the neoclassical distribution function, radial fluxes, and parallel flows and current.\textsuperscript{8,11} These formulae are nearly identical to the corresponding formulae for a tokamak. The formulae are explicit, in that they do not involve solutions of partial differential equations. In contrast, the corresponding formulae for a general stellarator must be expressed in terms of the solutions of partial differential equations involving the field strength.\textsuperscript{12–15} One example is the system of Eqs. (57)–(60) for the bootstrap current.

It is the purpose of this paper to demonstrate that perfect omnigenerity is another useful ideal limit. Omnigenerity, while less restrictive than quasisymmetry, is still a strong enough condition to place powerful constraints on $B(\theta, \zeta)$. For example, in the neighborhood of each minimum and maximum of $B$ along a field line, each adjacent field line segment on the flux surface has an extremum at the same value of $B$, as we will show in Sec. II using novel arguments. We will also show that field lines can never be parallel to the contours of $B$ on each flux surface, and these contours must topologically link the flux surface toroidally, poloidally, or both. By defining integers $M$ and $N$ as the number of times each contour links the plasma toroidally and poloidally, respectively, the helical “mode numbers” $M$ and $N$ in Eq. (1) can be generalized to any omnigenous plasma. Using this generalization, we will show in Sec. III that formulae for the bootstrap current and flux-surface-averaged parallel flow in a quasisymmetric plasma in fact apply to the larger class of all omnigenous plasmas. The formulae for the Pfirsch-Schlüter flow and current in a quasisymmetric plasma also apply to all omnigenous plasmas if a new term is added, consisting of an integral of derivatives of $B$. The same is true of the lowcollisionality distribution functions. Some of these neoclassical properties were discussed previously in Refs. 16–18 for the specific case of generalized poloidal symmetry ($M = 0$). Here, we give more general calculations that apply to omnigenerity of any helicity. In Refs. 16 and 17, it was pointed out that for an $M = 0$ omnigenous plasma, the bootstrap current vanishes unless there is inductive or RF-driven current. This result will be recovered from the analysis of general-helicity omnigenous fields here.

Another interesting feature of omnigenous magnetic fields that we will demonstrate concerns the radial electric field $E_r$. In a general stellarator, the radial electron and ion particle fluxes exhibit different dependencies on $E_r$. Consequently, it is possible to determine the electric field using the condition that the net radial current must vanish, i.e., quasi-neutrality or ambipolarity. However, this procedure fails in tokamaks or in quasisymmetric stellarators, which possess the property of “intrinsic ambipolarity.” This is the property that to leading order in the expansion of gyroradius to system size, the net radial current vanishes regardless of the radial electric field, and so the electric field is determined by higher-order processes that are more difficult to calculate. An omnigenous plasma that is far from quasisymmetry will not be intrinsically ambipolar, and so it is still possible to solve for $E_r$ using ambipolarity. In Sec. IV, we will derive $E_r$ for any omnigenous, non-quasisymmetric field. The result differs from previously known expressions for the electric field in non-omnigenous stellarators. Our calculation will also show from a new perspective that $E_r$ indeed becomes undetermined in the limit of quasisymmetry.

Finally, in Sec. V, we will derive some further geometric properties of $B(\theta, \zeta)$ for an omnigenous flux surface. It will be shown how to generate a family of omnigenous flux surfaces that are consistent with an additional symmetry usually possessed by stellarator experiments.

II. MAGNETIC FIELD PROPERTIES

\section{Extrema of $B$ on each flux surface}

Let us now begin to analyze the geometric properties of omnigenous fields in detail. Let $\bar{B}(r)$ and $\bar{B}(r)$ denote the nearest minimum and maximum of $B$ found by moving forward and backward along a field line from the starting position $r$. In a general stellarator, $\bar{B}$ and $\bar{B}$ will take on a continua of values (or several continua) on each flux surface. However, in an omnigenous field we will now show that $\bar{B}$ and $\bar{B}$ may only take on discrete values on each flux surface, and in the simplest case, each has only a single value on each flux surface. In other words, in the neighborhood of an extremum of $\bar{B}$ along a field line, each nearby field line segment on the same flux surface has an extremum at the same value of $B$.

Let us first prove this property for the minimum $\bar{B}$. We begin by recalling the contravariant and covariant expressions\textsuperscript{9} for $B$ in terms of the poloidal Boozer angle $\theta$ and the toroidal Boozer angle $\zeta$:

\begin{equation}
\vec{B} = \nabla\psi \times \nabla\theta + i\nabla\zeta \times \nabla\psi,
\end{equation}

\begin{equation}
\vec{B} = \beta(\theta, \zeta)\nabla\psi + I(\psi)\nabla\theta + G(\psi)\nabla\zeta.
\end{equation}

Here, $i$ is the rotational transform, $I(\psi)$ is $2/c$ times the toroidal current inside the flux surface $\psi$, and $G(\psi)$ is $2/c$ times the poloidal current outside the flux surface $\psi$. Now let $r_0 = (\theta_0, \zeta_0)$ denote a point at which $B$ is minimized with respect to movement along a field line. At this point, $\vec{B} \cdot \nabla B$ must vanish, so

\begin{equation}
0 = (\vec{B} \cdot \nabla\theta)(\partial B / \partial \theta) + (\vec{B} \cdot \nabla\zeta)(\partial B / \partial \zeta).
\end{equation}

If the field is omnigenous, deeply trapped particles at $r_0$ must have no radial drift. As $v_i \cdot \nabla\psi \not\propto \vec{B} \times \nabla\psi \cdot \nabla\psi$, then
Equations (4) and (5) are a system of two linearly independent equations for \( \partial B / \partial \theta \) and \( \partial B / \partial \zeta \) at \( r_0 \), so both of these derivatives must be zero. The vanishing of these derivatives implies \( B(r_0) \) is either an isolated local minimum, a saddle point, or one point along a “valley” of constant \( B \).

The first two of these three possibilities can be excluded as follows. We first Taylor-expand

\[
B \approx B_0 + \frac{x}{2}(\theta - \theta_0)^2 + y(\theta - \theta_0)(\zeta - \zeta_0) + \frac{z}{2}(\zeta - \zeta_0)^2,
\]

where \( x = [\partial^2 B / \partial \theta^2]_{\theta_0}, y = [\partial^2 B / \partial \theta \partial \zeta]_{\theta_0}, z = [\partial^2 B / \partial \zeta^2]_{\theta_0} \), and the zero subscripts indicate quantities evaluated at \( r_0 \).

Considering the variation of \( B \) along the nearby field line \( \theta = \theta_0 + (\zeta - \zeta_0) + \delta \) for some small \( \delta \), by eliminating either \( \theta \) or \( \zeta \) in Eq. (6) and completing the square, it is evident that \( B \) is minimized along the field line at the point \( r_1 = (\theta_1, \zeta_1) \), where \( \theta_1 = \theta_0 + (iy + z)\delta/A, \zeta_1 = \zeta_0 - (ix + y)\delta/A \) and \( A = r^2 + 2iy + z \). Plugging the definitions of \( \theta_1 \) and \( \zeta_1 \) into Eq. (6) gives

\[
B \approx B_0 + \frac{k\delta^2}{2A} + (\theta - \theta_1) \frac{k\delta}{A} - (\zeta - \zeta_1) \frac{ik\delta}{A} + \frac{x}{2}(\theta - \theta_1)^2 + y(\theta - \theta_1)(\zeta - \zeta_1) + \frac{z}{2}(\zeta - \zeta_1)^2,
\]

where \( k = xz - y^2 \). Since \( B \) is minimized along the shifted field line at \( r_1 \), the radial drift must vanish there, for the same reason it had to vanish at \( r_0 \), so \( \partial B / \partial \theta = 0 \) and \( \partial B / \partial \zeta = 0 \) at \( r_1 \). Consequently, the third and fourth right-hand-side terms in Eq. (7) (those linear in \( (\theta - \theta_1) \) and \( (\zeta - \zeta_1) \)) must vanish, and so \( k \) must be zero. Thus, the second term on the right hand side of Eq. (7) vanishes, and so the minimum of \( B \) along the shifted field line is \( B_0 \), the same as the minimum on the original field line. This proves the desired result for \( \dot{B} \).

This fact, that deeply trapped particles are perfectly confined when all \( B \) on a flux surface are the same, was first observed in Ref. 20.

Now we make the analogous argument for \( \dot{B} \). Let \( r_0 \) now represent a point at which \( B \) is maximized along a field line. The bounce time diverges for barely trapped particles, because they spend an infinitely long time near the turning points. Thus, if there is an outward radial drift at \( r_0 \), marginally trapped particles there will have an arbitrarily large radial excursion. Even if these particles would in principle make a large inward radial step at the opposite bounce point, they would drift out of the machine before having time to get to the other bounce point, so these particles effectively would have a nonzero time-averaged radial drift. We choose to include in the definition of omnigenity the condition that marginally trapped particles cannot have radial steps of unbounded size in this manner. Now suppose at \( r_0 \) there were an inward radial drift. By omnigenity, marginally trapped particles must make an arbitrarily large outward excursion elsewhere in the trajectory to balance the arbitrarily large inward excursion in the neighborhood of \( r_0 \), so this case too is unacceptable. Therefore, \( v_\theta, v_\psi \) must vanish at \( r_0 \), implying Eq. (5). The rest of the argument for the constancy of \( \dot{B} \) then applies, and so \( \dot{B} \) must be constant as well for each field line in a neighborhood of \( r_0 \) on the flux surface.

Due to these constraints on the extrema of \( B \), omnigenous fields represent an intermediate level of complexity between quasymmetric fields and general nonaxisymmetric fields. Figure 1 illustrates this point. For axisymmetric and quasymmetric fields, the \( B \) wells in which particles are trapped all have identical shape. At the opposite extreme of a general three-dimensional field, different field line segments have different maxima and minima of \( B \). Omnigenous fields represent a middle ground. Maxima of \( B \) occur repeatedly at the same values of \( B \), and the same is true of the minima. In fact, we will prove in Sec. II C that the maxima are equally spaced (in \( \theta \), in \( \zeta \), and in distance along the field), as indicated by the horizontal red arrows in Figure 1. Yet, unlike in quasymmetric fields, the shape of the \( B \) wells is different at different points along a field line.

B. Generalized helicity

In an omnigenous toroidal field, the constant-\( B \) contours on a flux surface must all encircle the plasma toroidally, poloidally, or both. In other words, each contour must topologically link the flux surface: a contour cannot be continuously deformable (homotopic) to a point without leaving the flux surface. If any constant-\( B \) contour did not link the flux surface in this manner, then the contour would enclose a point maximum or minimum of \( B \) within the surface, and we just proved that such point extrema cannot occur in an omnigenous field. As an illustration, the bold curve in Figure 2 is a \( B \) contour that does not link the plasma. This contour encloses a point minimum or maximum of \( B(r, \zeta) \) at \( \bar{P} \), and such points cannot exist in an omnigenous field. For contrast, Figure 3 depicts an omnigenous field, one in which the \( B \) contours encircle the plasma both poloidally and toroidally. Figure 4 shows an omnigenous field with toroidally closed \( B \) contours. Neither field has any point extrema of \( B \).

![FIG. 1. (Color online) Omnigenous fields have an intermediate level of complexity between quasymmetric and general nonaxisymmetric fields.](image-url)
We can also prove that all $B$ contours must encircle the plasma using the following alternative argument. If a constant-$B$ contour does not link the flux surface, then there will be points at which the contour is tangent to the field, such as point $T$ in Figure 2. (Recall that field lines are straight in the $(\theta, \zeta)$ plane for Boozer coordinates.) At such a point of tangency, $\mathbf{B} \cdot \nabla \mathbf{B} = 0$, but the derivative of $\mathbf{B}$ in any other direction on the flux surface is nonzero. Thus, Eq. (4) is satisfied, while Eq. (5) is not, violating the condition of omnigenity. Physically, if $\mathbf{B}$ is a maximum along the field line at $T$, deeply trapped particles at $T$ will have nonzero average radial drift, while if $\mathbf{B}$ is a maximum along the field line at $T$, barely trapped particles will make an infinite radial step when they bounce at $T$. Neither type of radial motion is allowed in an omnigenous field, so the $B$ contours of each flux surface in an omnigenous field can never be tangent to field lines. This implies the contours must link the plasma. It can be seen in Figures 3 and 4 that the $B$ contours are indeed nowhere tangent to the field lines.

We can now define integers $M$ and $N$ as follows: each $B$ contour closes on itself after traversing the torus $M$ times toroidally and $N$ times poloidally, that is, after $\theta$ increases by $2\pi N$ and $\zeta$ increases by $2\pi M$. This convention may seem backward at first, but it is consistent with the $M$ and $N$ defined earlier for a quasisymmetric field: $B = B(M0 - N\zeta)$. By defining $M$ and $N$ in terms of the topology of the $B$ contours as we have done, the helicity associated with quasisymmetric fields is generalized to any omnigenous field. Notice that this helicity is completely independent of the rotational transform $\iota$.

It should be noted that definition of the term “quasisymmetric” given by some authors is equivalent to the condition “omnigenous with $M = 0$.” However, other authors define “quasi-isodynamic” differently, as the case in which only particles with a particular value of normalized magnetic moment $\lambda = v_0^2 / (v^2 B)$ are omnigenous, not all particles.

Next, it will be convenient to define a field line label $\chi$ by

$$
\chi = (\theta - i\zeta) / (N - iM).
$$

This definition is convenient because if a constant-$B$ curve is followed until it closes on itself, then $\chi$ will increase by $2\pi$. For much of the analysis that follows we will use $(\psi, \chi, B)$ coordinates. In these coordinates, the magnetic field has a contravariant form $B = (N - iM) \nabla \psi \times \nabla \chi$ and a covariant form

$$
B = B_\psi \nabla \psi + B_\mathbf{B} \nabla \mathbf{B} + B_\chi \nabla \chi.
$$

The Jacobian is $\nabla \psi \times \nabla \mathbf{B} = (\mathbf{B} \cdot \nabla \mathbf{B}) / (N - iM)$. We now derive several properties of the covariant coefficients. The inner product of Eq. (9) with $\mathbf{B}$ gives $B_B = B^2 / \mathbf{B} \cdot \nabla \mathbf{B}$. The inner product of Eq. (9) with $\nabla \psi \times \nabla \chi$ gives

$$
B_\chi = - (N - iM) \frac{\mathbf{B} \times \nabla \psi \cdot \nabla \mathbf{B}}{\mathbf{B} \cdot \nabla \mathbf{B}}.
$$

As discussed in Sec. II A, the numerator of Eq. (10) vanishes whenever the denominator does, leaving $B_\chi$ nonsingular. Indeed, since omnigenity precludes $B$ contours from being tangent to field lines, then $\partial \psi / \partial \chi$ is never singular, and so $B_\chi = B \cdot \partial \mathbf{B} / \partial \chi$ cannot be singular. Here, and throughout this paper, $\partial / \partial \chi$ is performed at fixed $B$, $\partial / \partial B$ is performed
at fixed $\chi, \partial / \partial \theta$ is performed at fixed $\zeta$, and $\partial / \partial \zeta$ is performed at fixed $\theta$, unless denoted explicitly with a subscript.

Now consider a path on a flux surface that follows a constant-$B$ curve until it closes on itself. As described above, $\chi$ increases by $2\pi$ along this curve. From Ampère’s law, $(4\pi/c)i_h = \int \mathbf{B} \cdot d\mathbf{r} = \oint \mathbf{B} \cdot \mathbf{r} = \oint B_{\phi} d\chi$, where $i_h$ is the current linked by the loop, and the integrals are performed at constant $\psi$ and $B$. The integration path links the torus $N$ times poloidally and $M$ times toroidally, so the amount of current linked by this helical curve is $i_h = Ni_h + Mi_p$, where $i_h$ is the toroidal current inside the flux surface and $i_p$ is the poloidal current outside the flux surface. These currents are related to the coefficients of the Boozer covariant representation by $I = 2i_h/c$ and $G = 2i_p/c$. Therefore $i_h = c(MG + NI)/2$ and $i_p = G/2$. This application of Ampère’s law is illustrated in Figure 5 (for $M = 1$ and $N = 4$). Any single-valued function of position must be periodic in $\chi$ (with period $2\pi$), if $B$ is held fixed. In particular, $B_{\phi}$ must be periodic in this way, so we can write $B_{\phi} = MG + NI + \partial h / \partial \chi$ for some single-valued $h$. Hence, recalling Eq. (10), we obtain the useful formula

$$\frac{\mathbf{B} \times \nabla \psi \cdot \nabla \mathbf{B}}{\mathbf{B} \cdot \nabla \mathbf{B}} = -\frac{1}{(N - iM)} \frac{MG + NI + \partial h}{\partial \chi}. \quad (11)$$

In the quasisymmetric limit $B(\theta, \zeta) = B(M0 - N\zeta)$, then the left-hand side of this expression can be computed directly, and the result is the same but without the $h$ term. Thus, quasisymmetry corresponds to the $\partial h / \partial \chi = 0$ limit.

C. Relation between branches

The continuous coordinates $(\psi, \chi, B)$ do not uniquely determine a point in space, both because there may be multiple toroidal segments, but also because within each segment there are two points at given $B$ on either side of $\hat{B}$, the minimum of $B$ on the flux surface. This discrete degree of freedom, called the “branch,” will be denoted by $\gamma = \pm 1$. The shaded and unshaded regions of Figures 3 and 4 illustrate the two branches. The variations of $B$ in the two branches are related due to the condition of omnigenous. As shown in the Appendix A.

![Figure 5](image-url) FIG. 5. (Color online) Equation (11) is derived by applying Ampère’s law to a $B$ contour, such as the red curve here. The black arrows illustrate the toroidal and poloidal currents, which are the currents through the red and blue translucent surfaces, respectively.

This result was derived using different notation in Ref. 7 and is termed the “Cary-Shasharina Theorem” in Ref. 17.

Using Eq. (12), we can prove several facts about pairs of points on a same field line that share the same $B$ but lie on opposite sides of $\hat{B}$. Let $\Delta \chi$ be the distance between these points, measured along the field line. In a general stellarator, $\Delta \chi$ will depend on the field line label $\chi$ (in addition to $B$ and $\psi$). But since $\Delta \chi = \int_{\hat{B}}^{\hat{B}'} [\mathbf{b} \cdot \nabla \mathbf{B}]^{-1} dB'$ (i.e., $\mathbf{b} \cdot \nabla \mathbf{B}$ is evaluated at $B'$ rather than $\hat{B}$), then Eq. (12) implies $\Delta \chi / \partial \chi = 0$ in an omnigenous field. Thus, for any given $B$, every such pair of points has the same separation $\Delta \chi$. This result is illustrated for the case of $\hat{B}$, the maximum of $B$ on the flux surface, by the horizontal red arrows in Figure 1. A similar result holds for the difference in $\zeta$ between pairs of points. Let $\Delta \zeta = \int_{\hat{B}}^{\hat{B}'} \mathbf{b} \cdot \nabla \mathbf{B} dB'$ be the difference in $\zeta$ between a pair of points as described above. Notice $\partial \zeta / \partial \mathbf{b} \cdot \nabla \mathbf{B} = (\mathbf{b} \cdot \nabla \zeta) / \mathbf{b} \cdot \nabla \mathbf{B}$. Multiplying the covariant and contravariant Boozer representations (2) and (3),

$$B^2 / (G + i \ell) \nabla \psi \times \nabla \theta \cdot \nabla \zeta = \mathbf{B} \cdot \nabla \zeta = i^{-1} \mathbf{B} \cdot \nabla \theta. \quad (13)$$

Therefore,

$$\Delta \zeta = \frac{1}{G + i \ell} \int_{\hat{B}}^{\hat{B}'} \frac{\mathbf{b} \cdot dB'}{\mathbf{b} \cdot \nabla \mathbf{B}}, \quad (14)$$

which must be independent of $\chi$ due to Eq. (12). A similar proof shows the separation in $\theta$ between the points is also independent of field line. The results $\partial \Delta \chi / \partial \chi = 0$ and $\partial \Delta \chi / \partial \chi = 0$ are illustrated by the three arrows in Figure 4. These arrows point along $\mathbf{B}$, all joining two contours of the same $B$ on opposite sides of $\hat{B}$. As $\partial \Delta \chi / \partial \chi = 0$ and $\partial \Delta \chi / \partial \chi = 0$, these arrows must all have the same length.

It follows that the contours of $B = \hat{B}$ (where $\hat{B}$ is again the maximum $B$ on the flux surface) must in fact be straight lines in the $(\theta, \zeta)$ plane. The basis of the argument is that as $\Delta \chi(\hat{B})$ and $\Delta \zeta(\hat{B})$ are constants on a flux surface, then when the $\hat{B}$ contour is translated by $\Delta \chi(\hat{B})$ and $\Delta \zeta(\hat{B})$, it must lie on top of itself. In other words, the $\hat{B}$ contours must be symmetric under a translation along $\mathbf{B}$, shown by the arrow in Figure 3. Except for the uninteresting case in which $i$ is a special low-order rational number, the $\mathbf{B}$ contour cannot possibly have this symmetry unless it is straight. The rotational transform $i$ can be assumed to be irrational, since by continuity, $\mathbf{B}$ on any rational surface can differ only infinitesimally from $\mathbf{B}$ on a nearby irrational surface. To begin the rigorous proof, first consider the $M = 0$ case (poloidally closed $\mathbf{B}$ contours), and suppose the stellarator has $N_p$ identical toroidal segments with one $\mathbf{B}$ contour per segment. Let one $\mathbf{B}$ contour be given by $\zeta = \chi(\theta)$. If we shift this contour by $\Delta \chi(\hat{B})$ and $\Delta \zeta(\hat{B})$, it must lie on top of the next $\hat{B}$ contour, the one given by $\zeta = \chi(\theta) + (2\pi/N_p)$. Therefore, $\chi(\theta - 2\pi/N_p) + \Delta \chi = \chi(\theta) + (2\pi/N_p)$. Then, expanding $\chi$ as the Fourier series $\chi(\theta) = \sum_n \chi_n e^{in\theta}$, we can write
\[
\sum_n \gamma_n e^{i n \theta} (1 - e^{-i n \lambda}) = \Delta \text{c} - \frac{2\pi}{N_p}.
\] (15)

The \(n = 0\) component of this equation implies \(\Delta \text{c} = 2\pi/N_p\).
It follows that the exponent \(-i n \lambda\) will never be an integer multiple of \(2\pi i\) if \(i\) is irrational. Therefore, the quantity in parentheses in Eq. (15) can never be zero for \(n \neq 0\). Every \(n \neq 0\) component of Eq. (15) consequently implies \(\gamma_n = 0\), so \(\nabla(\theta)\) must be constant, meaning the \(B\) contours are straight. To apply the proof to fields in which both \(M\) and \(N\) are nonzero, all that is needed to redefine \(\nabla(\theta)\) as \(\nabla - M(\theta)/N\) along the \(B\) contour so \(\nabla\) remains periodic in \(\theta\). The proof can also be adapted to the \(N = 0\) case by switching the roles of \(\theta\) and \(\xi\).

Finally, it is important to consider both branches when forming the flux surface average in the \((\psi, \chi, B)\) coordinate system. For any quantity \(Q\), this average is given by

\[
(Q) = \frac{1}{V'} \int_0^{2\pi} \int_\psi^\phi dB \frac{Q}{B \cdot \nabla B},
\] (16)

where \(V' = \sum_n \gamma_n \int_\psi^\phi dB \frac{Q}{B \cdot \nabla B}\).

### D. Departure from quasisymmetry

For the remainder of this section, we develop several properties related to \(\partial h/\partial \xi\), a quantity that represents the departure from quasisymmetry. These properties will generalize results discussed in Ref. 18. First, plugging Eq. (9) into the MHD equilibrium relation \(0 = \nabla \psi \cdot \nabla \times B\), we find \(\partial B_\psi/\partial \xi = \partial B_f/\partial B\). Plugging in our earlier expressions for \(B_f\) and \(B_\chi\), then

\[
(\partial/\partial \xi)(B^2 / B \cdot \nabla B) = \partial^2 h / \partial B \partial \xi.
\] (17)

Applying \(\sum_n \gamma_n\) and recalling Eq. (12), then \(\sum_n \gamma_n \partial^2 h / \partial B \partial \xi = 0\). Now integrate this expression in \(B\) from \(\bar{B}\) to \(B\). As \(\partial h/\partial \xi\) is continuous everywhere, it is continuous at \(\bar{B}\), and so it must be branch-independent at \(\bar{B}\). Therefore, the contribution from the integration boundary at \(\bar{B}\) vanishes. Consequently,

\[
\sum_n \gamma_n \partial h / \partial \xi = 0.
\] (18)

In other words, \(\partial h/\partial \xi\) is branch-independent everywhere.

Any quantity that is continuous and branch-independent must be a constant along the curve \(B = \bar{B}\). This result applies in particular to \(\partial h/\partial \xi\), for which the constant must be zero, or else \(\sum_0^{2\pi} d\theta \partial h / \partial \xi\) would be nonzero. Thus, \(\partial h/\partial \xi\) must vanish along \(B = \bar{B}\).

Now we derive expressions to relate the new quantity \(\partial h/\partial \xi\) to more familiar Boozer coordinates. Using Eq. (13),

\[
\frac{B^2}{B \cdot \nabla B} = \left( G + i \frac{\partial B}{\partial \xi} + i \frac{\partial B}{\partial \theta} \right)^{-1}.
\] (19)

In addition, using \((d\xi/d\theta)_{\xi} = i^{-1}\) gives

\[
\frac{\partial B}{\partial \xi} = \frac{\partial B}{\partial \xi} + \frac{i}{\partial \xi} \frac{\partial B}{\partial \theta},\n\] (20)

where subscripts on partial derivatives indicate quantities held fixed. Combining this result with Eq. (19),

\[
\frac{B^2}{B \cdot \nabla B} = \left( G + i \frac{\partial B}{\partial \xi} + i \frac{\partial B}{\partial \theta} \right)^{-1}.
\] (21)

Next, we form \(B \times \nabla \psi \cdot \nabla B = (\nabla \psi \times \nabla \chi)(G(\partial B / \partial \theta) - I(\partial B / \partial \xi))\). Combining this result with Eq. (19) gives

\[
\frac{B \times \nabla \psi \cdot \nabla B}{B \cdot \nabla B} = \left( G \frac{\partial B}{\partial \theta} - I \frac{\partial B}{\partial \xi} \right) \left( \frac{\partial B}{\partial \xi} + i \frac{\partial B}{\partial \theta} \right)^{-1}.
\] (22)

Substituting for the left-hand side using Eq. (11), after some manipulation we obtain

\[
\frac{\partial h}{\partial \xi} = -(G + i) \left[ M + (N - iM) \left( \frac{\partial B}{\partial \xi} + i \frac{\partial B}{\partial \theta} \right)^{-1} \left( \frac{\partial B}{\partial \theta} \right) \right],
\] (23)

This expression allows explicit calculation of \(\partial h/\partial \xi\) for a given \(B(\theta, \xi)\). As an example, Figure 6 shows \(\partial h/\partial \xi\) calculated using this formula for the example field of Figure 3.

Finally, we derive some additional formulae for \(\partial h/\partial \xi\) that will be used later. From \(\partial h/\partial \theta = 1/(N + iM)\), we find \(\partial B_f/\partial \theta = (\partial B_f/\partial \theta)_\psi + (N - iM)^{-1}(\partial B_f/\partial \xi)_\psi\). Plugging this result into Eq. (23) gives

\[
\frac{\partial h}{\partial \xi} = \left[ N + \frac{(\partial B_f/\partial \xi)_\psi}{(\partial B_f/\partial \theta)_\psi} \right] \left( G + i \right) \frac{\partial h}{\partial \xi} = \left( G + i \right) \left( \frac{\partial \theta}{\partial \xi} - N \right),
\] (24)

where the second equality follows from \(0 = (\partial B_f/\partial \theta)_B = (\partial B_f/\partial \theta)_\psi + (\partial B_f/\partial \xi)_\psi (\partial B_f/\partial \xi)\). Applying \(\partial h/\partial \xi\) to Eq. (8), we find \(\partial h/\partial \xi = N - i(\partial \xi / \partial \xi) - iM\). When inserted into Eq. (24), this gives
\[
\frac{\partial h}{\partial \chi} = (G + d) \left( \frac{\partial \zeta}{\partial \chi} - M \right) .
\] (25)

Comparing either Eq. (24) or (25) with Eq. (21), it is evident that Eq. (17) is satisfied.

Expressions (23)–(25) will be used in Sec. III A to calculate the Pfirsch-Schlüter flow and current.

### III. PARALLEL FLOW AND CURRENT

We now move on to analyzing the physical properties of omnigenous plasmas. First we will derive general properties of the flow and current for any collisionality. Then, we will calculate the flow and current explicitly for the long-mean-free-path regime.

#### A. Form of the flows and current

Consider the density \( n \) and flow velocity \( V \) of a single species. We take \( n \) to be a flux function to leading order and take the perpendicular flow to be given by the sum of \( E \times B \) and diamagnetic flows. Then, the flow must satisfy \( 0 = \mathbf{V} \cdot \mathbf{V} = \mathbf{B} \times \mathbf{V} (V_x / B) + \omega \mathbf{B} \times \mathbf{V} \psi \cdot \mathbf{V}(1/B^2) \), where \( \omega = c(d\Phi_0/d\psi) + c(dp/d\psi) (\text{Zen})^{-1} \), \( \Phi_0 = \left< \Phi \right> \) is the flux surface average of the electrostatic potential \( \Phi \), \( p \) is the species pressure and a flux function to lowest order, and we have used the fact that \( \mathbf{V} \cdot (\mathbf{B} \times \mathbf{V}) = 0 \) for MHD equilibrium. Now define \( U \) to be the single-valued and continuous solution of

\[
\mathbf{B} \cdot \mathbf{V}(U/B) = \mathbf{B} \times \mathbf{V} \psi \cdot \mathbf{V}(1/B^2),
\] (26)

with the integration constant chosen so that \( \left< UB \right> = 0 \). The solubility condition of Eq. (26) is satisfied for any MHD equilibrium. Then \( 0 = \mathbf{B} \cdot \mathbf{V} (V_x + \omega U)/B \), so \( V_x + \omega U = A(\psi) B \) for some unknown \( A \), which can be eliminated by multiplying the last equation by \( B \) and flux surface averaging. Thus,

\[
V_x = \left< V_x B / B^2 \right> - \omega U.
\] (27)

To solve for \( U \), we use Eqs. (11), (26), and \( \mathbf{B} \cdot \mathbf{V} = (\mathbf{B} \cdot \mathbf{V} B / B^2) \) to obtain

\[
\frac{\partial}{\partial B} \left( \frac{U}{B} \right) = 2 B^3 (N - i M) \left( MG + N I + \frac{\partial h}{\partial \chi} \right).
\] (28)

Integrating,

\[
U = \frac{1}{B} \left( \frac{MG + NI}{B^2} \right) \left[ \frac{2}{N - i M} \int \frac{dB'}{B'^3} \frac{\partial h'}{\partial \chi} \right] + Y(\psi),
\] (29)

where \( Y(\psi) \) is an integration constant. The limit of integration has been chosen to ensure \( Y \) is continuous, which can be seen as follows. The parallel flow \( V_x \) has a term proportional to \( U \) (in Eq. (27)), so \( U \) must be continuous everywhere. At \( B = \hat{B} \), then \( U \) must be independent of \( \gamma \), and so from Eq. (29), \( Y \) then must be independent of \( \gamma \) (since the other terms are all \( \gamma \)-independent). Next consider that with the possible exception of \( Y \), all the other terms in Eq. (29) are continuous across the curve \( B = \hat{B} \) at fixed \( 0 \) (or, in the \( N = 0 \) case, at fixed \( \zeta \)). Therefore, \( Y \) must have this same property. Therefore, \( Y \) must be independent of \( \gamma \).

The unknown \( Y \) can be determined by multiplying Eq. (29) by \( B^2 \) and flux surface averaging. Defining

\[
W(\psi, \gamma, B) = 2B^2 \int \frac{dB'}{B'} \frac{\partial h'}{\partial \chi},
\] (30)

then

\[
U = -\frac{1}{B(N - i M)} \left[ (MG + NI) \left( 1 - \frac{B^2}{B'^2} \right) + W \right].
\] (31)

To obtain this result we have used \( \langle W \rangle = 0 \). Indeed, it can be verified that \( \langle W(\psi, B) \rangle = 0 \) for any function \( \phi(\psi, B) \) as follows. First, using Eqs. (12) and (18), we find

\[
\sum_i \int_0^{2\pi} d\varphi \frac{1}{B} \frac{\partial h}{\partial \chi} = \left< \sum_i \frac{\gamma}{\mathbf{B} \cdot \mathbf{V}B} \left( \int_0^{2\pi} d\varphi \frac{\partial h}{\partial \chi} \right) \right> = 0,
\] (32)

where the last equality follows because the last term in parentheses is zero. Examining the form of the flux surface average in Eq. (16), it can be seen that \( (W(\phi(\psi, B))) \) is proportional to the leftmost expression in Eq. (32), so it vanishes.

Using Eq. (31), the parallel flow is

\[
V_x = \frac{\langle V_x B / B^2 \rangle}{B^2} + V_x^{PS},
\] (33)

where

\[
V_x^{PS} = \frac{c}{B(N - i M)} \left( \frac{d\Phi_0}{d\psi} + \frac{1}{\text{Zen}} \frac{dp}{d\psi} \right) \times \left[ \left( 1 - \frac{B^2}{B'^2} \right) (MG + NI) + W \right].
\] (34)

Summing over species \( a \) to form \( j_x = \sum_a Z_a e_n V_x \), and using quasi-neutrality,

\[
j_x = \frac{\langle j_x B / B^2 \rangle}{B^2} + j_x^{PS},
\] (35)

where

\[
j_x^{PS} = \frac{c}{B(N - i M)} \left( \frac{dp_e}{d\psi} \right) \left[ \left( 1 - \frac{B^2}{B'^2} \right) (MG + NI) + W \right],
\] (36)

and \( p_e \) is now the total pressure \( \sum_a p_a \). Notice that Eqs. (33)–(36) are valid for any collisionality regime.

In a general stellarator, the Pfirsch-Schlüter flow and current can only be defined implicitly, in terms of the solution of the magnetic differential equation (26). In omnigenous fields, in contrast, the flow and current may be written explicitly, in terms of the integral of the field strength \( W \).
We now describe two approaches to efficiently calculate $W$ for a given $B(\theta, \zeta)$.

In the first approach, the integration variable in Eq. (30) is changed to $\theta$ using Eq. (20), and then Eq. (23) is applied, giving $W = 2B^2(G + u)w/\partial z$, where

$$w = \int_{0}^{\bar{\theta}} \frac{d\theta'}{(\bar{B}(\bar{z}))^2} \left( M \frac{\partial B'}{\partial \zeta} + N \frac{\partial \theta'}{\partial \theta} \right) = \int_{\zeta}^{\hat{\zeta}} \frac{d\zeta'}{(\hat{B}(\hat{\zeta}))^2} \left( M \frac{\partial B'}{\partial \zeta} + N \frac{\partial B'}{\partial \theta} \right).$$

(37)

Here, $\hat{\theta}$ and $\hat{\zeta}$ represent the values of $\theta$ and $\zeta$ associated with $B = \bar{B}$. Notice the integrals in Eq. (37) are evaluated along constant-$\zeta$ paths (field lines).

In an alternative approach, Eq. (24) or (25) is substituted into Eq. (30) to obtain

$$w = \int_{\hat{B}}^{\bar{B}} \frac{d\theta'}{(\hat{B}(\hat{z}))^2} \left( \frac{\partial \zeta}{\partial \theta} - M \right) = \int_{\hat{B}}^{\bar{B}} \frac{d\theta'}{(\hat{B}(\hat{z}))^2} \left( \frac{\partial \theta}{\partial \zeta} - N \right).$$

(38)

Numerical root-finding can be used to compute $\zeta(\chi, B)$ or $\theta(\chi, B)$ from a given $B(\theta, \zeta)$, and the result used to compute either of the integrals in Eq. (38). Figure 7 shows $W$ computed by either of these methods for the magnetic field of Figure 3.

### B. Long-mean-free-path regime

Explicit formulae for $\langle V|B \rangle$ and $\langle j|B \rangle$ are now derived in the long-mean-free-path regime. We begin with the drift-kinetic equation

$$v_{||} \cdot b + v \cdot \nabla \psi \frac{\partial \rho_0}{\partial \psi} + \frac{Ze v_{||} \rho_0}{T} b \cdot \nabla \Phi_0 = C\{f_1\},$$

(39)

where $C$ is the linearized collision operator and $\Phi_0 = \Phi - \Phi_0$. In Eq. (39) and hereafter, the independent velocity-space variables are $\lambda = v_{||}^2/(Bv^2)$ and the leading-order total energy $mv^2/2 + Ze \Phi_0$.

It is useful to next define $\Delta$ by the relation

$$v_{||} \cdot \nabla \psi = v_{||} b \cdot \nabla \Delta.$$  

(40)

The radial magnetic drifts must have such a form because, from the definition of omnigenuity, $v_m \cdot \nabla \psi$ vanishes upon a transit or bounce average. Observing $B \times k \cdot \nabla = b \times VB \cdot \nabla \psi$ (this is an exact relation for any MHD equilibrium, not a low-$\beta$ approximation) then $v_m \cdot \nabla \psi = -(B \times VB \cdot \nabla \psi)(v_{||}/B)\partial /\partial B(v_{||}/\Omega)$. Then, Eqs. (11) and (40) imply

$$\frac{\partial \Delta}{\partial B} = -\frac{1}{(N - \bar{M})} \left( MG + NI + \frac{\partial \partial \psi}{\partial \zeta} \right) \frac{\partial v_{||}}{\partial B \Omega}.$$  

(41)

Integrating in $B$, we find

$$\Delta = \left( \frac{MG + NI}{\Omega} \right) \frac{v_{||}}{\Omega} + S,$

(42)

where

$$S = \frac{1}{N - \bar{M}} \int_{\hat{B}}^{\bar{B}} \frac{d\theta}{b_{||}} \frac{\partial}{\partial \zeta} \frac{\partial v_{||}}{\partial B},$$

(43)

and $B_\perp = \hat{B}$ if $\lambda < 1/\hat{B}$ and $B_\perp = 1/\lambda$ otherwise. The limit of integration is chosen this way for passing particles ($\lambda < 1/\hat{B}$) so that $\Delta$ is continuous in position space across the curve $B = \hat{B}$, and the limit of integration for trapped particles ($\lambda > 1/\hat{B}$) is chosen so that $\Delta$ is continuous in velocity space at $\lambda = 1/\hat{B}$.

Thus, the kinetic equation may be written

$$v_{||} b \cdot \nabla g = C\{f_1\},$$

(44)

where

$$g = f_1 + \Delta \frac{\partial \rho_0}{\partial \psi} + \frac{Ze \Phi_0}{T} \rho_0.$$  

(45)

By annihilating $g^{(1)}$ in this equation, a constraint is obtained that determines $g^{(0)}$. Just as in the tokamak calculation, $g^{(0)} = 0$ is a solution in the trapped part of phase space. For the passing part of phase space, the annihilation operation is $\langle B|v_{||}\rangle(\cdot \cdot)$. Recalling Eq. (16), the constraint equation becomes

$$0 = \frac{1}{V^2} \sum \gamma \int_{0}^{2\pi} d\zeta \int_{\hat{B}}^{\bar{B}} \frac{dB}{v_{||} \hat{B} \cdot \hat{VB}} C\left( g^{(0)} - \Delta \frac{\partial \rho_0}{\partial \psi} \right).$$

(46)

We next argue that the $S$ term in $\Delta$ (in Eq. (42)) may be dropped in Eq. (46). The collision operator may be written as derivatives and integrals involving $v$ and $\xi = \sigma \sqrt{1 - \lambda^2}$, where $\sigma = \text{sgn}(v_{||})$, so $C$ does not introduce any dependence on $\chi$ or $\gamma$. Thus, the contribution to Eq. (46) from the $\partial \partial \psi /\partial \zeta$ term in $\Delta$ is proportional to the leftmost expression in
Eq. (32), so it vanishes. The constraint equation, therefore, reduces to

$$0 = \left( B \left\{ g^{(0)} - \left( \frac{M G + N I}{m - N} \right) v_i \frac{\partial f_0}{\partial \psi} \right\} \right). \quad (47)$$

This equation is identical to the one solved for a tokamak, aside from the constant factor in parentheses. We now show that the parallel flow associated with the distribution function $f_1$ is consistent with the forms (33) and (34) found in Sec. III A from a fluid approach. Forming $d^3 v f = - n V$ using Eq. (44) and taking $g \approx g^{(0)}$,

$$n V = \frac{c n}{B} \left( \frac{d\Phi_0}{d\psi} + \frac{1}{Z e} \frac{d\rho}{d\psi} \right) \left( \frac{M G + N I}{N - m} \right) + \frac{3 B^2 / 4}{N - m} \int_0^{1/B} d\lambda \int_0^0 d\beta \beta \left( 2 - \beta^B \right) \left( \frac{1}{1 - \beta^B} \right), \quad (48)$$

where $X = \int d^3 v g$. Noting

$$\int d^3 v Q = \frac{\pi B}{2} \sum_\sigma \int_0^{1/B} d\lambda \int_0^{\infty} d\beta \left( \frac{1}{1 - \beta^B} \right) \frac{d^3 v Q}{\lambda_||}, \quad (49)$$

for any $Q$, the upper limit of the $\lambda$ integral can be changed to $1/B$ in the integral for $X$ because $g = 0$ in the trapped region. Thus, $X$ varies with position only through the factor $B$, so $X$ has the form of the $\left\langle V B / B^2 \right| B^2 \rangle$ term in Eq. (33). Next, the $\lambda$ integral in Eq. (48) can be evaluated by moving it inside the $B^2$ integral. In this exchange, the range of the $\lambda$ integration becomes $(0, 1/B^2)$ and the range of the $B^2$ integral becomes $(B, B)$. When the $\lambda$ integral is evaluated, the result is identical to the $W$ term in Eq. (34). Consequently, the parallel flow (48) evaluated from kinetic theory has precisely the spatial dependence calculated from fluid theory in Eqs. (33) and (34).

For the ions in a pure plasma, $g$, and $X$ can be calculated explicitly using the momentum-conserving model collision operator $C_i = \nu \mathcal{L} \left\{ f_1 - f_0 m_n u v_|| / T_i \right\}$, where

$$\mathcal{L} = \frac{2 v_i}{B \lambda_||} \frac{\partial}{\partial \lambda_||} \frac{v_i}{\lambda_||} \frac{\partial}{\partial \lambda} \quad (50)$$

is the Lorentz pitch-angle scattering operator,

$$u = \left( \int d^3 v_{i0} \frac{m_i v_i^2 \nu}{2 T_i} \right)^{-1} \int d^3 v_{i0} v_||, \quad (51)$$

$$\nu = \frac{2 \pi Z^2 e^4 n_i \ln \Lambda \left| \text{erf}(x) - \Psi(x) \right|}{\sqrt{2 m_i T_i}}, \quad (52)$$

$$\Psi(x) = \left[ \text{erf}(x) - x (\text{derf}(x) / dx) / (2x^2) \right] \left( 2 / \sqrt{\pi} \right)^{1/2} \int_0^x \exp(-t^2) dt \text{ is the error function, and } x = v / \sqrt{2 T_i / m_i}.$$

This model operator captures the dominant effect of collisions for large aspect ratio. The solution of Eq. (47) is performed exactly as for the tokamak calculation, giving

$$g^i = \frac{f_0}{B} \left( \frac{(M G + N I) v_i}{(m - N) Z e T_i} \right) \left( \frac{m_i v_i^2}{2 T_i} - 1.33 \right) \times \frac{e^4}{2 \lambda} \int_0^{1/B} d\lambda \left( \frac{\lambda}{\sqrt{1 - \beta^B}} \right) \left( \frac{\lambda}{\lambda} \right), \quad (53)$$

where $H = H(B^{-1} - \lambda)$ is a Heaviside function which is 1 for passing particles and 0 for trapped particles. Thus, the ion parallel flow for low collisionality is

$$V = -1.17 \frac{f_0}{B} \left( \frac{(M G + N I) v_i}{(N - m) Z e T_i} \right) \left( \frac{d\Phi_0}{d\psi} + \frac{1}{Z e} \frac{d\rho}{d\psi} \right), \quad (54)$$

where

$$f_0 = \frac{3}{4} \left( B^2 \right) \left( \frac{1}{\lambda} \right) \left( \frac{\lambda}{\sqrt{1 - \beta^B}} \right) \quad (55)$$

is the effective fraction of circulating particles.

When the average parallel ion flow $\langle V \rangle$ is evaluated from Eq. (54), the $W$ term—the only term that reflects the departure from quasisymmetry—does not contribute due to Eq. (32). The resulting expression for $\langle V \rangle$ in an omnigenous plasma is identical to the corresponding formula for a quasisymmetric stellarator. It can be seen that the bootstrap current $\langle J \rangle$ in an omnigenous stellarator must also be given by the same expression as in a quasisymmetric stellarator. To understand this result, first recall that the perturbed distribution function of each species is given by $f_1 = g^{(0)} + Z e \Phi_0 f_0 / T + \Delta \partial f_0 / \partial \psi$, with $\Delta$ given by Eq. (42), and $g^{(0)}$ the solution of Eq. (47). The $S$ term in $\Delta$ does not contribute to $\langle V \rangle$ for the species as we have seen due to Eq. (32). Also, $g^{(0)}$ must be the same as in a quasisymmetric stellarator, since in the equation that determines it, Eq. (47), the departure from quasisymmetry does not appear. Thus, $\langle V \rangle$ for each species is the same as in a quasisymmetric device, and so $\langle j \rangle$ is the same as well. The result is

$$\langle j \rangle = \frac{f_0}{Z (\sqrt{2} + Z)} \left( \frac{(M G + N I) v_i}{(N - m)} \right) \left( \frac{d\rho}{d\psi} + \frac{1}{Z e} \frac{d\psi}{d\psi} \right) - \frac{2.07 Z + 0.88}{a} \frac{n_i}{d\psi} \frac{dT_i}{d\psi} - 1.17 \frac{n_i}{Z} \frac{dT_i}{d\psi}, \quad (56)$$

where $f_0 = 1 - f_e$ is the effective trapped fraction, $a = Z^2 + 2.21 Z + 0.75$, and $Z$ is the ion charge. To obtain Eq. (56), the method of page 207 of Ref. 22 can be employed, using the approximate Spitzer function from Appendix B of Ref. 24 with two Laguerre polynomials. The tokamak expressions for $\langle V \rangle$ and $\langle j \rangle$ can be recovered from the omnigenous/quasisymmetric stellarator expressions by simply setting $N = 0$.

The expression (56) can also be derived by solving the differential equations for the bootstrap current in a general stellarator, derived using the Shaing-Callen moment.
In this approach, the bootstrap current in a general stellarator for a pure \( Z = 1 \) plasma is given by
\[
\langle j_1 \rangle = -1.70 c f_i \mathcal{L} (G_{hi}) \left( \frac{dp_i}{dy} + \frac{dp_j}{dy} - 0.75 n \frac{dT_e}{dy} - 1.17 n \frac{dT_i}{dy} \right),
\]
where the “geometric factor” is
\[
\langle G_{hi} \rangle = \frac{1}{f_i} \left( \frac{\lambda}{g_2} \frac{3}{4} (B_2^2) \right)^{1/2} \frac{\lambda (g_3)}{\langle g_1 \rangle} d\lambda,
\]
g1 = \sqrt{1 - \lambda B}, g2 is the solution of
\[
B \cdot \nabla (g_2/B_2^2) = B \times \nabla \psi \cdot \nabla (1/B_2^2)
\]
such that \( g_2 = 0 \) when \( B = \tilde{B} \), and \( g_4 \) is the solution of
\[
B \cdot \nabla (g_4/g_1) = B \times \nabla \psi \cdot \nabla (1/g_1)
\]
for any \( \lambda \) in the range \( [0, 1/B] \) such that \( g_4 = 0 \) when \( B = \tilde{B} \). Equation (59) for \( g_2 \) closely resembles Eq. (26) for \( U \) which we solved earlier. Using the solution (31), then
\[
g_2 = \frac{1}{N - iM} \left[ (MG + NI) \left( \frac{B_2^2}{B_2^2} - 1 \right) - W \right].
\]
Equation (60) for \( g_4 \) may be solved in the same manner used to find \( U \) in Eqs. (26)–(31), yielding
\[
g_4 = \frac{MG + NI}{N - iM} \left[ \frac{1}{\sqrt{1 - \lambda B}} \right] - 1 + \frac{\lambda}{2} \frac{d B'}{\sqrt{1 - \lambda B}} \frac{d \theta'}{\sqrt{1 - \lambda B}}.
\]
Evaluating Eq. (58), the \( W \) term in \( g_2 \) and the \( \theta' \) term in \( g_4 \) vanish upon flux surface averaging due to Eq. (32). Then evaluating the \( \lambda \) integral, we obtain \( \langle G_{hi} \rangle = (MG + NI)/(iM - N) \), which is precisely the result for a quasisymmetric stellarator. Then, Eq. (57) for \( f_i \ll 1 \) reduces to the \( Z = 1 \) limit of Eq. (56), proving the two approaches are consistent.

Equation (56) gives the current density on one flux surface in terms of \( I \) and \( G \), which represent the total poloidal and toroidal current through a suitable surface (times 2/c). By writing \( I \) and \( G \) as the appropriate integrals of the current density, as shown in the Appendix C, two ordinary differential equations (C3) and (C4) can be derived that give \( I \) and \( G \) in terms of \( \langle j_1 \rangle \). These two equations, together with Eq. (56), constitute a complete system of equations for the self-consistent-current profile.

The case \( M = 0 \) (generalized quasi-poloidal symmetry) is noteworthy, for then the substitution of Eq. (56) into Eq. (C3) gives \( dl/d\psi = (...)l \). As the boundary condition for \( I \) is that it vanishes on the magnetic axis, then the self-consistent profile of \( I(\psi) \) is \( I = 0 \), and so \( \langle j_1 \rangle = 0 \) everywhere. Thus, we recover the result of Refs. 16–18 that the bootstrap current in an \( M = 0 \) omnigenous device vanishes. (If Ohmic or RF-driven current is present, there will be additional contributions to \( \langle j_1 \rangle \) besides Eq. (56), providing an inhomogeneous term in the differential equation for \( I(\psi) \), so \( I \) and the bootstrap current would become nonzero.) In contrast, for any omnigenous plasma with \( M \neq 0 \), the contribution from \( G \) to the bootstrap current is still present. As \( G \) has a nonzero boundary condition at the plasma edge, then \( G \) will generally be nonzero, and so the bootstrap current will also be nonzero.

IV. RADIATIONAL ELECTRIC FIELD

In a non-quasisymmetric stellarator, there is usually only one special value of the radial electric field \( E_r \) at each radius for which the electron and ion particle fluxes will be equal. In equilibrium, \( E_r \) must therefore take on this value. (If the electron temperature \( T_e \) is much higher than the ion temperature \( T_i \), a second “electron root” solution may also be possible, but we will assume \( T_e \sim T_i \), excluding this possibility.) In this section, we will determine \( E_r \) for the case of ions in the long-mean-free-path regime.

We begin by finding the radial particle flux of each species, allowing general collisionality for the moment. By applying \( \langle B^2 \rangle \times \nabla \psi \cdot (\ldots) \) to the fluid momentum equation with a diagonal pressure tensor, the particle flux is found to be \( \langle \Gamma \cdot \nabla \psi \rangle = \Gamma_m + \Gamma_e + \Gamma_i \), where \( \Gamma_m = \frac{1}{\sqrt{1 - \lambda B}} \int dz \mu \nu m \cdot \psi \) and \( \Gamma_e = \langle n_c B^{-2} \times \nabla \Phi \cdot \nabla \psi \rangle \), and \( \Gamma_i = \langle \mu \nabla \psi \cdot \nabla \psi \cdot \nabla \psi \rangle \). We thereby obtain
\[
\langle \Gamma \cdot \nabla \psi \rangle \approx -\left( \int d^3 v \Delta C(f) \right).
\]
This result holds for any collisionality regime.

Next, we flux-surface-average the quasineutrality equation \( \nabla \cdot j = 0 \) to obtain \( 0 = (\nabla \cdot \psi) = \sum_a Z_a e \langle \Gamma_a \cdot \nabla \psi \rangle \), where \( a \) is the particle species. We consider a pure plasma with ion charge \( Z \) and comparable electron and ion temperatures. In this case, the ion contribution to the radial current is larger than the electron contribution by \( \sim \sqrt{m_e/m_i} \), so the leading-order ambipolarity constraint is \( \langle \Gamma \cdot \nabla \psi \rangle = 0 \). We henceforth assume all quantities refer to ions and drop the subscripts.

Specializing to the long-mean-free-path regime, we may apply the model collision operator from Eqs. (50)–(52), appropriate for large aspect ratio. Using the momentum conservation property \( \int d^3 v \nu |C(f) = 0 \),
\[
\langle \Gamma \cdot \nabla \psi \rangle = -\left( \int d^3 v S(V) \left( g - \Delta \frac{\partial f_0}{\partial \psi} - f_0 \frac{\mu a v}{T} \right) \right).
\]
We now exploit the fact that $\langle \partial Q / \partial \chi \rangle = 0$ for any $Q$ that is independent of branch and $\chi$. This fact follows from Eqs. (16) and (32). Thus, only the terms in Eq. (64) that are quadratic rather than linear in $\partial h / \partial \chi$ will contribute. For instance, $g$ will not contribute since it is constant on a flux surface. Keeping only the nonvanishing terms, we may write $(\Gamma \cdot \nabla \psi) = \Gamma_1 + \Gamma_2$ where

$$\Gamma_1 = \left\langle d^3 v S v \mathcal{L} \left( s \frac{\partial \tilde{f}_0}{\partial \psi} \right) \right\rangle,$$

$$\Gamma_2 = \left\langle d^3 v S v \mathcal{L} \left( f_0 \frac{mv^2 u_x}{T} \right) \right\rangle,$$

and

$$u_x = - \left( \int d^3 v f_0 \frac{mv^2}{3T} \right)^{-1} \int d^3 v \frac{\partial \tilde{f}_0}{\partial \psi} |v| S,$$

is the part of $u$ that depends on $\chi$. Applying Eq. (49), it can be seen that $\Gamma_1$ and $u_x$ are both proportional to the integral $\int_0^L \int d^3 v d^3 w \partial \tilde{f}_0 / \partial \psi$. Therefore, $\Gamma_2$ and the total radial flux are proportional to the same factor. The ambipolarity condition can thus be written

$$0 = (\Gamma \cdot \nabla \psi) \propto \left( \int_0^{\pi} \frac{\partial h}{\partial \chi} \frac{\partial h'}{\partial \chi'} \right) \int_0^\infty d^3 v \mathcal{L} \frac{\partial \tilde{f}_0}{\partial \psi},$$

where the single and double primes refer to the integration variables in the $S$ factors. In a quasisymmetric or axisymmetric plasma, $\partial h / \partial \chi = 0$ and so the equation is automatically satisfied. However, in a non-quasisymmetric omnigenous field, the $\chi$ integral in Eq. (68) is generally nonzero, so the $v$ integral following it must vanish. This condition may be written

$$0 = \int_0^\infty d^4 e^{-x^2 - y^2} \left[ \frac{1}{p} \frac{dp}{d\psi} + \frac{Ze}{T} \frac{d\tilde{f}_0}{d\psi} + \left( x^2 - \frac{5}{2} \right) \frac{dT}{d\psi} \right],$$

which may be solved for the radial electric field $d\tilde{f}_0 / d\psi$. Reinstating the species subscripts for completeness, the result is

$$\frac{d\tilde{f}_0}{d\psi} = \frac{Ze}{T} \left( - \frac{1}{p} \frac{dp}{d\psi} + \frac{1}{T} \frac{dT}{d\psi} \right),$$

where

$$1.17 = \frac{5}{2} - \left( \int_0^\infty d^4 e^{-x^2 - y^2} \right)^{-1} \int_0^\infty d^4 \phi e^{-x^2 - y^2} \tilde{f}_0 \tilde{f}_1,$$

is the same numerical constant that appears in the banana-regime tokamak ion flow and in Eq. (54). This electric field differs from previously known results for a non-omnigenous stellarator. For example, if the main ions in a non-omnigenous device are in the $1/\nu$ regime of collisionality, the relation (70) holds but with 1.17 replaced by 2.37 (see, e.g., Equation (35) of Ref. 25).

Assuming the temperature scale length is not dramatically shorter than the density scale length, Eq. (70) gives an inward electric field. Physically, this field develops to electrostatically confine the ions, reducing their radial flux to the much smaller level of the electron flux.

As the departure from omniguity increases, Eq. (70) will become inapplicable before the formulae for the flow and current do, since the particles with nonzero average radial drift will contribute strongly to the radial particle flux but not to the parallel transport.

V. CONSTRUCTING STELLARATOR-SYMMETRIC OMNIGENOUS FIELDS

In this section, we will give a construction for $B(\theta, \zeta)$ field strength patterns that both satisfy all the omniguity conditions and also satisfy stellarator symmetry, meaning the invariance of $B$ under the replacements $\theta \rightarrow -\theta, \zeta \rightarrow -\zeta$. A construction of omnigenous $B(\theta, \zeta)$ was given previously in Ref. 7, but that procedure generally produces fields without stellarator symmetry, whereas every stellarator experiment to our knowledge does possess stellarator symmetry (aside from small error fields).

The fields we will construct are designed to have the following omniguity properties: (1) The $B$ contours will all link the torus, (2) the $B$ contour will be straight, and (3) $\partial \Delta_\zeta / \partial \zeta = 0$ and $\partial \Delta_\theta / \partial \theta = 0$. Here, $\Delta_\zeta$ and $\Delta_\theta$ are the same quantities discussed following Eq. (14): the separations in $\zeta$ and $\theta$ between the pair of points on opposite branches of a field line but at the same $B$. The other omniguity properties from Sec. II will then follow automatically. For example, by applying $\partial^2 / \partial B \partial \psi$ to Eq. (14), then Eq. (12) follows.

We will now present the construction, and we will verify afterward that it indeed produces fields that are omnigenous and stellarator-symmetric. The construction is given in terms of new angles $\tilde{\theta}$ and $\tilde{\zeta}$, such that consecutive maxima of $B$ lie on the constant-$\tilde{\theta}$ curves $\tilde{\zeta} = 0$ and $\tilde{\zeta} = 2\pi$. We also employ an effective rotational transform $\tilde{i}$, equal to $\partial \tilde{\theta} / \partial \tilde{\zeta}$ along the field. To construct an omnigenous field with nonzero $N$ and with $N_N$ toroidal periods, the new quantities are related to the original quantities by $\tilde{\theta} = \theta, \tilde{\zeta} = (N_N - M_0)N_p$, and $\tilde{i} = \tilde{i} / \left( [N - sM]N_p \right)$. To construct an omnigenous field with $(M, N) = (1, 0)$ and $N_p$ toroidal periods, then instead $\tilde{\theta} = \tilde{N}_p \zeta, \tilde{\zeta} = 0$, and $\tilde{i} = \tilde{i} / \tilde{N}_p$. In either case, a stellarator-symmetric $B$ is one invariant under $\tilde{\theta} \rightarrow -\tilde{\theta}$ and $\tilde{\zeta} \rightarrow -\tilde{\zeta}$.

Also, $\partial \Delta_\zeta / \partial \zeta = 0$ is equivalent to $\partial \Delta_\zeta / \partial \zeta = 0$, where $\Delta_\zeta$ is defined just as for $\Delta_\zeta$, but using $\tilde{\zeta}$ in place of $\zeta$.

There are several inputs to the construction. First, we may pick $\tilde{B}$ and $\tilde{B}$. Second, we choose a function $D(x)$ which will turn out to be closely related to $\Delta_s(B)$. The function $D(x)$ must be defined on the domain $[0, \pi]$ and must satisfy $D(0) = s$ and $D(\pi) = 0$. Finally, we choose a function $s(x, y)$ which will represent the $\tilde{\zeta}$-variation of the $B$ contours. We require $s(x, y)$ to be both odd in $y$ and $2\pi$-periodic in $y$ (i.e., the Fourier series for $s$ contains sin(ny) terms but no cos(ny) terms or y-independent term). The input $x$ ranges over $[0, \pi]$, and we require $s(0, y) = 0$ for all $y$.

It is then useful to introduce a new coordinate $\eta$ which resembles $B$ but which is different in the two branches. Specifically, we define $\eta \in [0, 2\pi]$ through the relation

$$B = \tilde{B}(1 + \epsilon + \epsilon \cos \eta),$$

(72)
where \( \epsilon = (\dot{B} - \ddot{B})/(2\dot{B}) \). Notice from Eq. (72) that \( \eta = 0 \) along \( \zeta = 0 \) (where \( B = B \)) and \( \eta = 2\pi \) along \( \zeta = 2\pi \) (where \( B \) again rises to \( B \)). While \( B \) contours coincide with \( \eta \) contours in the \( (\theta, \zeta) \) plane, \( \eta \) lies in the range \( 0 \leq \eta < \pi \) on one branch, while \( \eta \) lies in the range \( \pi < \eta \leq 2\pi \) on the other branch.

We then compute \( \zeta \) as follows:

\[
\tilde{\zeta}(\eta, \dot{\theta}) = \begin{cases} 
\pi - s\left( \eta, \dot{\theta} + iD(\eta) \right) - D(\eta) & \text{if } 0 \leq \eta \leq \pi \\
\pi + s\left( 2\pi - \eta, -\dot{\theta} + iD(2\pi - \eta) \right) + D(2\pi - \eta) & \text{if } \pi < \eta \leq 2\pi.
\end{cases}
\]  

(73)

Numerical root-finding is next used to compute the inverse map \( \eta(\theta, \zeta) \), and finally \( B \) is calculated by Eq. (72).

Figures 3 and 4 show omnigenous stellarator-symmetric fields constructed using the above procedure. For Figure 3, the parameters are chosen to resemble HSX: \( M = 1, N = 4, N_p = 1, \iota = 1.05, \) and \( \iota = 0.072 \). The numerical functions used are \( s(x, y) = 0.4x\sin(y) \) and \( D(x) = \pi - x \). Figure 8 shows the associated \( \eta(\theta, \zeta) \) function. For Figure 4, \( M = 1, N = 0, N_p = 3, \iota = 1.62, = 0.1, s(x, y) = 0.15x\sin(y) \) and \( D(x) = \pi - x \).

We now prove that the \( B \) resulting from the above construction is stellarator-symmetric and omnigenous, beginning with stellarator symmetry. Thinking of \( B \) as an independent variable in place of \( \zeta \), we can restate the definition of this symmetry as follows: when \( \dot{\theta} \rightarrow -\dot{\theta} \), and \( B \) remains constant, and the branch is reversed, then \( \zeta \) must go to \( -\zeta \). Reversing the branch at constant \( B \) is equivalent to the replacement \( \eta \rightarrow 2\pi - \eta \). Adding factors of \( 2\pi \) to keep \( \theta \) and \( \zeta \) within the range \([0, 2\pi]\), we can therefore write the stellarator symmetry criterion as

\[ \tilde{\zeta}(\eta, \dot{\theta}) = 2\pi - \tilde{\zeta}(2\pi - \eta, 2\pi - \dot{\theta}). \]  

(74)

If \( \eta \leq \pi \), then the left-hand side of this equation is given by the top line of Eq. (73), and the right-hand side of Eq. (74) is given by the bottom line of Eq. (73). It can be immediately verified that Eq. (74) is indeed satisfied. Similarly, if \( \eta > \pi \), then the left-hand side of Eq. (74) is given by the bottom line of Eq. (73), while the right-hand side of Eq. (74) is given by the top line of Eq. (73), and the satisfaction of Eq. (74) is immediate.

VI. CONCLUSIONS

The limit of a single-helicity (i.e., quasisymmetric) field is a useful point of reference for insight into stellarator physics, for in these effectively 2D fields, analytic calculations can be carried out more completely than in a general stellarator. In the preceding sections, we have shown that omnigenous plasmas ought to be another such point of reference. Many geometrical and physical properties of omnigenous plasmas are either identical to the associated quantity in a quasisymmetric plasma, or else obtained by the addition of one term that is strongly constrained. While every quasisymmetric field is omnigenous, in practice, not every omnigenous field is quasisymmetric. Therefore, a broader attention to the larger class of omnigenous fields may allow better optimization for other criteria such as smaller aspect ratio or coil simplicity. Furthermore, it is omnigentness and not quasisymmetry that is the necessary condition for confinement of alpha particles. Any viable fusion reactor will need to be
nearly omnigenous in order to prevent damage to the first wall from unconfined alphas. Indeed, alpha particle confinement time is routinely used as an optimization criterion in stellarator design codes. As alpha confinement becomes increasingly important in future reactor-relevant experiments, stellarator designs can be expected to more closely approach omnigenity. The recent design study in Ref. 16 gives one example of a nearly omnigenous device.

In Sec. II, novel proofs were given of various geometric properties of omnigenous magnetic fields. The $B$ contours must link the flux surface toroidally, poloidally, or both, so no isolated extrema of $B$ on the flux surface are allowed. The field lines can never be tangent to the $B$ contours. The curve of $B$ (the maximum of $B$) must be straight in Boozer coordinates. The variation of $B$ on the two branches is constrained by Eq. (12). The integers $M$ and $N$ usually defined by the quasisymmetry relation $B = B(M0 - N\zeta)$ may be generalized to any omnigenous field by redefining them as the number of times each $B$ contour encircles the plasma toroidally and poloidally. In Eq. (11), it was shown that the ratio $(B \times V_{\parallel} \cdot \hat{\psi})/|B| \cdot VB$, which arises repeatedly in transport calculations, may be written as a sum of a quasisymmetric part and a departure from quasisymmetry, $\partial h/\partial \xi$.

This same division into quasisymmetric and non-quasisymmetric components also arises in physical quantities. The Pfirsch-Schlueter flow and current Eqs. (33) and (36) are given by the same formulae as in a quasisymmetric plasma. For each of the quantities discussed above, formulae for a quasisymmetric plasma can be recovered by setting $\partial h/\partial \xi \rightarrow 0$, and tokamak formulae can be recovered by also setting $N \rightarrow 0$ and $M \rightarrow 1$.

In general, a self-consistent current profile may be found by calculating the current density in terms of the total current using kinetic theory, and then writing the current density as an inverse Jacobian. Noting that the inverse Jacobian is $1/\sqrt{\varepsilon}$, we thereby obtain

$$v_{m} \cdot \dot{\mathbf{v}} = \left(\frac{\partial}{\partial \varepsilon}\right)_{\varepsilon} \left(\mathbf{v}_{\varepsilon} \cdot \mathbf{V}_{\varepsilon}ight) - \left(\mathbf{v}_{\varepsilon} \cdot \mathbf{V}_{\varepsilon}ight) \left(\mathbf{v}_{\varepsilon} \cdot \mathbf{B}\right).$$

(A1)

Next, we define the bounce average, which for any quantity $A$ is

$$\mathcal{A} = \mathcal{T} \sum_{k} \frac{1}{2} \left(\langle v_{\varepsilon} \cdot \mathbf{V}_{\varepsilon} \rangle \right)^{-1} A d\zeta',$$

where $\tau = 2 \int_{-\zeta}^{\zeta} \langle v_{\varepsilon} \cdot \mathbf{V}_{\varepsilon} \rangle^{-1} d\zeta'$, $\sigma = \text{sgn}(v_{\varepsilon})$, and $\zeta_{-}$ and $\zeta_{+}$ are the two bounce points (at which $v_{\parallel} = 0$). The integrals in the bounce
average are performed at constant $x$. Applying the bounce average to Eq. (A1) gives $\overline{\nabla_m \cdot \nabla \psi} = mc_0 \frac{\partial J}{\partial x}$. 
Equation (A3) is true for any $x$ in the interval $(\bar{B}, \bar{B})$. We now divide Eq. (A3) by $\sqrt{y-x}$, where $y$ is any value in the same interval, and we integrate over $x$ from $\bar{B}$ to $y$. Interchanging the order of the $x$ and $B$ integration, the $x$ integral becomes $\int_{\bar{B}}^y dx \sqrt{x-B}/(y-x) = (\pi/2)(y-B)$, giving $X = \int_{\bar{B}}^y dB (y-B) S(B)$. Differentiating twice with respect to $y$ gives $X = S(y)$. We had allowed $y$ to be any value in the interval $(\bar{B}, \bar{B})$, so $S$ must vanish everywhere, proving the theorem.

APPENDIX B: QUASISYMMETRY IN VARIOUS COORDINATE SYSTEMS

In this appendix, we prove that $B$ has a single helicity in Boozer coordinates if and only if $B$ has a single helicity in Hamada coordinates. While one proof can be found in Ref. 28, here we prove a more general result, that symmetry is equivalent for any straight-field-line coordinate system in which the Jacobian is a function only of $\psi$ and $B$.

A number of identities must be demonstrated before the main theorem is proved. Begin by considering two sets of coordinates, $(\theta_s, \zeta_s)$ and $(\theta_y, \zeta_y)$, which are not necessarily Boozer or Hamada coordinates. If the coordinates are straight-field-line coordinates, then $B = \nabla \psi \times \nabla \theta_s + i \nabla \zeta_s \times \nabla \psi = \nabla \psi \times \nabla \theta_s + i \nabla \zeta_s \times \nabla \psi$, where $2\pi n \psi$ is the toroidal flux. Suppose the transformation from one system to the other is written as $\theta_y = \theta_s + \mathcal{F}(\psi, \theta_s, \zeta_s), \zeta_y = \zeta_s + \mathcal{G}(\psi, \theta_s, \zeta_s)$, where $\mathcal{F}$ and $\mathcal{G}$ are periodic in both the poloidal and toroidal angles. Then

$$\nabla \psi \times \nabla \mathcal{F} + i \nabla \mathcal{G} \times \nabla \psi = 0.$$  (B1)

The $\nabla \theta_s$ component of this equation tells us $\partial \mathcal{F}/\partial \zeta_s = i \partial \mathcal{G}/\partial \zeta_s$, so upon integrating, $\mathcal{F} = i \mathcal{G} + \psi(\theta_s, \zeta_s)$ for some integration constant $\psi$. Here and throughout this appendix, $\partial/\partial \zeta_s$ holds $\theta_s$ fixed, $\partial/\partial \theta_s$ holds $\zeta_s$ fixed, $\partial/\partial \zeta_y$ holds $\theta_y$ fixed, and $\partial/\partial \theta_y$ holds $\zeta_y$ fixed. The $\nabla \zeta_y$ component of Eq. (B1) implies $\partial \mathcal{F}/\partial \theta_s = i \partial \mathcal{G}/\partial \theta_y$, so $\mathcal{F} = i \mathcal{G} + w(\psi, \theta_y)$ for some integration constant $w$. By comparing these two relations between $\mathcal{F}$ and $\mathcal{G}$, $\mathcal{F}$ must equal $i \mathcal{G}$ plus a flux function, so

$$\theta_y = \theta_s + i \mathcal{G} + A(\psi) \quad \text{and} \quad \zeta_y = \zeta_s + \mathcal{G}$$  (B2)

for some flux function $A(\psi)$.

Now suppose the Jacobian for the $(\theta_y, \zeta_y)$ coordinates varies on a flux surface only through $B$, that is, $\nabla \psi \cdot \nabla \theta_y \times \nabla \zeta_y = A_y(\psi, B)$ for some function $A_y$. Notice both Boozer and Hamada coordinates have this property. Suppose the analogous property also holds for the $(\theta_s, \zeta_s)$ coordinates: $\nabla \psi \cdot \nabla \theta_s \times \nabla \zeta_s = A_s(\psi, B)$ for some function $A_s$. Then

$$\nabla \psi \cdot \nabla \theta_s \times \nabla \zeta_s = \frac{A_s}{A_s} \nabla \psi \cdot \nabla \theta_s \times \nabla \zeta_s.$$  (B3)

Next, we apply the chain rule to $\mathcal{G}$ from Eq. (B2)

$$\frac{\partial \mathcal{G}}{\partial \theta_y} = \frac{\partial \theta_y}{\partial \theta_s} \frac{\partial \mathcal{G}}{\partial \theta_s} + \frac{\partial \zeta_y}{\partial \theta_s} \frac{\partial \mathcal{G}}{\partial \zeta_s}.$$  (B4)

By applying $\partial/\partial \theta_y$ to Eq. (B2), we find $1 = \frac{\partial \theta_y}{\partial \theta_s} \frac{\partial \mathcal{G}}{\partial \theta_s} + i \frac{\partial \zeta_y}{\partial \theta_s} \frac{\partial \mathcal{G}}{\partial \zeta_s}$, so Eq. (B4) implies

$$\frac{\partial \mathcal{G}}{\partial \theta_y} = \left(1 + i \frac{\partial \zeta_y}{\partial \theta_s} \frac{\partial \mathcal{G}}{\partial \zeta_s}ight) \frac{\partial \mathcal{G}}{\partial \theta_s} = \frac{\partial \mathcal{G}}{\partial \zeta_s}.$$  (B5)

Rearranging,

$$\left(1 + i \frac{\partial \zeta_y}{\partial \theta_s} \frac{\partial \mathcal{G}}{\partial \zeta_s}ight) = \frac{\partial \mathcal{G}}{\partial \zeta_s}.$$  (B6)

Now, apply $B \cdot \nabla$ to Eq. (B2) to obtain $\nabla \psi \cdot \nabla \theta_y \cdot \nabla \zeta_y = \nabla \psi \cdot \nabla \theta_s \cdot \nabla \zeta_s + B \cdot \nabla \mathcal{G}$. Noting (B3), then

$$\frac{A_s}{A_s} = 1 + i \frac{\partial \zeta_y}{\partial \theta_s} \frac{\partial \mathcal{G}}{\partial \zeta_s}.$$  (B7)

Substituting this expression into Eq. (B6) then gives

$$\frac{A_s}{A_s} \frac{\partial \mathcal{G}}{\partial \theta_y} = \frac{\partial \zeta_y}{\partial \theta_s} \frac{\partial \mathcal{G}}{\partial \zeta_s}.$$  (B8)

Repeating the steps from Eqs. (B4)–(B6) but applying $\partial/\partial \zeta_y$, we can similarly derive

$$\frac{A_s}{A_s} \frac{\partial \mathcal{G}}{\partial \theta_y} = \frac{\partial \mathcal{G}}{\partial \zeta_s}.$$  (B9)

Next, applying $\partial/\partial \theta_s$ to Eq. (B7),

$$\frac{\partial A_s}{\partial B A_s} \frac{\partial B}{\partial \theta_s} = \left(1 + i \frac{\partial \zeta_y}{\partial \theta_s} \frac{\partial \mathcal{G}}{\partial \zeta_s}ight) \frac{\partial \mathcal{G}}{\partial \zeta_s}.$$  (B10)

Recalling that $B \cdot \nabla = \nabla \psi \times \nabla \theta_s \cdot \nabla \zeta_s [(\partial/\partial \zeta_s) + i (\partial/\partial \theta_s)]$, then Eq. (B10) is equivalent to
\[
B \cdot \nabla \frac{\partial G}{\partial \theta_x} = \left( A_x \frac{\partial}{\partial B A_x} + A_y \frac{\partial}{\partial B A_y} \right) \frac{\partial B}{\partial \theta_x}.
\] (B11)

We could have applied \( \partial / \partial \zeta_x \) to Eq. (B7) instead of \( \partial / \partial \theta_x \), and so it is also true that
\[
B \cdot \nabla \frac{\partial G}{\partial \zeta_x} = \left( A_x \frac{\partial}{\partial B A_x} + A_y \frac{\partial}{\partial B A_y} \right) \frac{\partial B}{\partial \zeta_x}.
\] (B12)

We are finally prepared to begin the main proof. Suppose \( B \) has only a single helicity in the \((\theta_x, \zeta_x)\) coordinates: \( B = B(M\theta_x - N\zeta_x) \) for some integers \( M \) and \( N \), or equivalently, \( N \partial B / \partial \theta_x + M \partial B / \partial \zeta_x = 0 \). Then, from Eqs. (B11) and (B12), \( B \cdot \nabla(N \partial G / \partial \theta_x + M \partial G / \partial \zeta_x) = 0 \). It follows that \( N \partial G / \partial \theta_x + M \partial G / \partial \zeta_x = S(\psi) \) for some flux function \( S(\psi) \). Integrating this result in \( \theta_x \) and \( \zeta_x \) from 0 to \( 2\pi \) in both variables, we find \( S \) must be zero. Then, applying Eqs. (B8) and (B9),
\[
N \partial G / \partial \theta_x + M \partial G / \partial \zeta_x = 0.
\] (B13)

Finally, we form
\[
N \frac{\partial B}{\partial \theta_x} + M \frac{\partial B}{\partial \zeta_x} = N \left( \frac{\partial \theta_x}{\partial \theta_x} \frac{\partial B}{\partial \theta_x} + \frac{\partial \zeta_x}{\partial \theta_x} \frac{\partial B}{\partial \zeta_x} \right) \\
+ M \left( \frac{\partial \theta_x}{\partial \zeta_x} \frac{\partial B}{\partial \theta_x} + \frac{\partial \zeta_x}{\partial \zeta_x} \frac{\partial B}{\partial \zeta_x} \right) \\
= N \left( 1 - \frac{\partial G}{\partial \theta_x} \frac{\partial B}{\partial \theta_x} - \frac{\partial G}{\partial \zeta_x} \frac{\partial B}{\partial \zeta_x} \right) \\
+ M \left( -\frac{\partial G}{\partial \zeta_x} \frac{\partial B}{\partial \theta_x} + 1 - \frac{\partial G}{\partial \zeta_x} \frac{\partial B}{\partial \zeta_x} \right).
\] (B14)

The first equality above is the chain rule, and to get the second equality we have used the \( \partial / \partial \theta_x \) and \( \partial / \partial \zeta_x \) derivatives of Eq. (B2). The final expression of Eq. (B14) vanishes due to Eq. (B13), and so
\[
N \frac{\partial B}{\partial \theta_x} + M \frac{\partial B}{\partial \zeta_x} = 0 \Rightarrow N \frac{\partial B}{\partial \theta_x} + M \frac{\partial B}{\partial \zeta_x} = 0.
\] (B15)

The right equality in Eq. (B15) also implies the left one, since \( x \) and \( y \) can be interchanged in the proof. For the specific case that \((\theta_x, \zeta_x)\) are Boozers, and \((\theta_x, \zeta_x)\) are Hamada angles, then \( B \) has a single helicity in the former if and only if \( B \) has a single helicity in the latter.

**APPENDIX C: CURRENT IN A GENERAL STELLARATOR**

Here, we calculate several relations which are satisfied by the current in any MHD equilibrium with nested toroidal flux surfaces. We begin by noting that the perpendicular current is \( j_{\perp} = c(dI_{\psi}/d\psi)B^{-1} \times \nabla \psi \), where \( p_2 \) is the sum of the pressures of each species and a flux function.

Next, recall that the coefficient \( I(\psi) \) in the covariant Booser representation (3) equals \( 2/c \) times the toroidal current inside a flux surface. Therefore, \( I(\psi) = (2/c) \int d^2 a \cdot j \), where the surface integral is performed over a constant-\( \zeta \) cross-section of the plasma, a surface which covers the region from magnetic axis out to the flux surface \( \psi \). The area element is \( d^2 a = d\psi d\theta (\nabla \psi \cdot \hat{r} \times \nabla \psi)^{-1} \) \( d\zeta \).

Using \( j = (j_\perp / B) + j_\parallel \) and Eqs. (2) and (3), we obtain
\[
I = \frac{2}{c} \int \psi \left( -c \frac{d I_{\psi}}{d\psi} \int_0^{2\pi} d\theta \frac{1}{B^2} + \int_0^{2\pi} d\theta \frac{j_\parallel}{B} \right),
\] (C1)

where everything in parentheses is evaluated at \( \psi \) rather than \( \psi \). We next integrate Eq. (C1) over all \( \zeta \). Recall that the flux surface average in Boozer coordinates can be written
\[
\langle x \rangle = \int_0^{2\pi} d\theta \int_0^{2\pi} d\zeta \langle x / B^2 \rangle \int_0^{2\pi} d\theta \int_0^{2\pi} d\zeta \langle 1 / B^2 \rangle,
\] (C2)

and observe that \( \langle B^2 \rangle = 4\pi j_\parallel / \int_0^{2\pi} d\theta \int_0^{2\pi} d\zeta \langle 1 / B^2 \rangle \). Then, differentiating Eq. (C1) in \( \psi \), we can write
\[
\frac{dI}{d\psi} + \frac{4\pi j_\parallel}{\langle B^2 \rangle} = \frac{4\pi}{c} \frac{\langle j_\parallel B \rangle}{\langle B^2 \rangle}.
\] (C3)

The boundary condition for this equation is \( I = 0 \) at the magnetic axis.

An analogous ordinary differential equation for \( G(\psi) \) can be derived by repeating the above analysis with a constant-\( \theta \) surface:
\[
\frac{dG}{d\psi} + 4\pi G \frac{dI_{\psi}}{d\psi} = \frac{4\pi}{c} \frac{\langle j_\parallel B \rangle}{\langle B^2 \rangle}.
\] (C4)

The boundary condition for \( G \) is that it must go to its vacuum value at the plasma edge.

If another equation for \( \langle j_\parallel B \rangle \) in terms of \( I \) and \( G \) can be obtained from kinetic theory (as we have done for an omnigenous stellarator in Eq. (56)), then this equation can be used with Eqs. (C3) and (C4) to calculate a self-consistent current profile.
